**PRIORITY
DOCUMENT**

SUBMITTED OR TRANSMITTED IN
COMPLIANCE WITH RULE 17.1(a) OR (b)

I, the undersigned, being an officer duly authorised in accordance with Section 74(1) and (4) of the Deregulation & Contracting Out Act 1994, to sign and issue certificates on behalf of the Comptroller-General, hereby certify that annexed hereto is a true copy of the documents as originally filed in connection with the patent application identified therein.

In accordance with the Patents (Companies Re-registration) Rules 1982, if a company named in this certificate and any accompanying documents has re-registered under the Companies Act 1980 with the same name as that with which it was registered immediately before re-registration save for the substitution as, or inclusion as, the last part of the name of the words "public limited company" or their equivalents in Welsh, references to the name of the company in this certificate and any accompanying documents shall be treated as references to the name with which it is so re-registered.

In accordance with the rules, the words "public limited company" may be replaced by p.l.c., plc, P.L.C. or PLC.

Re-registration under the Companies Act does not constitute a new legal entity but merely subjects the company to certain additional company law rules.

Warning

After an application for a patent has been filed, the Comptroller of the Patent Office will consider whether publication or communication of the invention should be prohibited or restricted under Section 22 of the Patents Act 1977. You will be informed if it is necessary to prohibit or restrict your invention in this way. Furthermore, if you live in the United Kingdom, Section 23 of the Patents Act 1977 stops you from applying for a patent abroad without first getting written permission from the Patent Office unless an application has been filed at least 6 weeks beforehand in the United Kingdom for a patent for the same invention and either no direction prohibiting publication or communication has been given, or any such direction has been revoked.

Notes

- If you need help to fill in this form or you have any questions, please contact the Patent Office on 0645 500505.
- Write your answers in capital letters using black ink or you may type them.
- If there is not enough space for all the relevant details on any part of this form, please continue on a separate sheet of paper and write "see continuation sheet" in the relevant part(s). Any continuation sheet should be attached to this form.
- If you have answered 'Yes' Patents Form 7/77 will need to be filed.
- Once you have filled in the form you must remember to sign and date it.
- For details of the fee and ways to pay please contact the Patent Office.

TELECONFERENCING SYSTEM

This invention relates to audio teleconferencing systems. These are systems in which three or more participants, each having a telephone connection, can participate in a multi-way discussion. The essential part of a teleconference system is called the conference "bridge", and is where the audio signals from all the participants are combined. Conference bridges presently function by receiving audio from each of the participants, appropriately mixing the audio signals, and then distributing the mixed signal to each of the participants. All signal processing is concentrated in the bridge, and the result is monaural (that is, there is a single sound channel). This arrangement is shown in Figure 1, which will be described in detail later. The principal drawback with this system is that the audio quality is monophonic, generally poor, it is very difficult to determine which participants are speaking at any one time, especially when the number of participants is large.

According to the invention, there is provided a teleconferencing system comprising a conference bridge having a multichannel connection to each customer equipment, the customer equipment having means to separately process each channel to provide an output, preferably spatialised, representing each of the other participants. Preferably the conference bridge comprises a concentrator, having means to identify the currently active input channels and to transmit only those active channels over the multichannel connection, together with control information identifying the transmitted channels. This reduces the capacity required by the multichannel connection. The control information identifying the active channels may be carried in a separate control channel, or as an overhead on the active subset of channels. In a preferred arrangement the channel representing a given participant is excluded from the output provided to that participant. This may be achieved by excluding that channel from the processing in the customer equipment, but is preferably achieved by excluding it from the multichannel transmission from the bridge to that participant, thereby reducing further the capacity required by the multichannel connection.

Exemplary embodiments of the invention will now be described, by way of example, with reference to the drawings, in which:

Figure 1 illustrates a conventional teleconference system;

Figure 2 illustrates a spatial audio teleconference system according to one embodiment of the invention;

Figure 3 illustrates a N-channel speech decoder used in the embodiment of Figure 2;

5 Figure 4 illustrates a N-Channel audio spatialiser used in the embodiment of Figure 2;

Figure 5 illustrates a second embodiment of the invention;

Figure 6 illustrates how the invention may be used with conventional PSTN channels;

10 Figure 7 illustrates a variant of the invention for use with a video conference system;

Figure 8 illustrates a voice switched concentrator which may be used in the embodiments of the invention.

Figures 9, 10, and 11 illustrate various echo cancellation techniques.

15 In the conventional system illustrated in Figure 1 the conference bridge located in the exchange equipment 100 receives signals from the various customer equipments 10, (20, 30 not shown) in response to sounds detected by respective microphones 11, 21, 31 etc. These signals are transmitted over the telephone network (1), to the exchange 100 at which the bridge is established. Generally the
20 signals will travel by way of a local exchange (not shown) in which the analogue signals are converted to digital form, usually employing linear companding such as "A law" (as used for example in Europe) or "mu-Law" (as used for example in the United States of America) for onward transmission to the bridge exchange 100. On arrival at the bridge exchange 100, the bridge passes each incoming signal 11, 21,
25 31 through a respective digital converter 111, 112, 113 to convert them from A Law to linear digital signals, and then passes the linear signals to a digital combiner 120 to generate a combined signal. This combined signal is re-converted to A law in a further digital converter 110, and the resulting signal transmitted over the telephone network (2) to each customer equipment 10, (20, 30) for conversion to
30 sound in respective loudspeakers 12, 22, 32 etc. In this way the exchange equipment 100 acts as a "bridge" to allow one or more customer equipments 32 to connect into a simple two-way connection between customer equipments 10, 20.

The systems illustrated in Figures 2 to 8 replace the conventional conference bridge system of Figure 1 with a multicast system in which several channels can be transmitted to each participant, using a multi-channel link comprising an uplink 3, and a downlink comprising a control channel 4 and a digital audio downlink 5 comprising several channels 51, 52. Participants with suitable equipment can then process these channels 51, 52 in various ways as will be described.

The transmission medium used for the uplink 3 and downlink 4,5 can be any suitable medium. ISDN (Integrated Services Data Network) technology or LAN (Local Area Network) - respectively public and private data networks - are the favoured transmission options since they provide adequate data rate and low latency - delays due to coding and transmission buffering. However, they are expensive and so far have a low penetration in the market place. Internet Protocol techniques are more widely used, but have poor latency and unreliable data rates. Being packet systems, they are less suited to voice applications. It is also possible to use the conventional PSTN (public switch telephone system) with a speech band modem. The latest internet type modems provide up to 56kbit/s downstream (links 4,5: digital network down to the customer via local loop), and up to 28.8kbit/s upstream (link 3). They are low cost and are commonly bundled into PC packages. Ideally a system should be able to work with all of the above, and with standard analogue PSTN available as a backup.

The signal mixing can take place either in the user's terminal equipment, or in a centralised processing platform as shown in Figure 2. In Figure 2 the customer equipment 10 contains a microphone 11 and loudspeaker system 12 as before. However, the loudspeaker system 12 is a spatialised system - that is, it has two or more channels to allow sounds to appear to emanate from different directions. This may take the form of stereophonic headphones, or a more complex system such as disclosed in United States Patents 5533129 (Gefvert), 5307415 (Fosgate), article "*Spatial Sound for Telepresence*" by M.Hollier, D. Burraston, and A. Rimell in the *British Telecom Technology Journal*, October 1997 or the applicant's own pending European Patent Application 97304218.7 filed on 17th June 1997.

The output from the microphone 11 is encoded by an encoder 13 forming part of the customer equipment 10, and transmitted over the uplink 3 to the

exchange equipment 100. Here it is combined with the other input channels 21, 31 from the other participants into a concentrator 230 which combines the various inputs into an audio signal having a smaller number of channels 51, 52. These channels are transmitted over multiple-channel digital audio links 5 to the customer equipments 10, (20, 30) where they are first decoded by respective decoders 14, 24, 34 and provided to a spatialiser 15 for controlling the mixing of the channels to the generate a spatialised signal in the speaker equipment 12.

The concentrator 230 selects from the input channels 11, 21, 31 those carrying useful information - typically those carrying speech, and passes only these over the return link 5. This reduces the amount of information to be carried. A control channel 4 carries data identifying which channels were selected. The spatialiser 15 uses data from the control channel to identify which of the original sound channels 11, 21, 31 it is receiving, and on which of the "N" channels 51, 52 in the audio link each original channel is present, and constructs a spatialised signal using that information. The spatialised signal can be tailored to the individual customer, for example the number of talkers in the spatialised system, the customer's preferences as to where in the spatialised system each participant is to appear to be located, and which channels to include; for example the original talker or a simultaneous translation. In particular, the user may exclude the channel representing his own input 11.

Transmission efficiency is achieved because only the active subset N of the total number of channels M are transmitted at any one time. The subset is chosen using a voice controlled dynamic channel allocation algorithm in the N:M concentrator 230. A possible implementation of this is shown in Figure 8. Each input channel 11, 21, 31 is monitored by a respective analyser 231, 232, 233. As shown for analyser 231, the signal is subjected to a speech detection and analysis process 231b. This detects whether speech is present on the respective input 11, and gives a confidence value, indicative of how likely the signal contains speech. This ensures that low-level background speech is given a lower weight than speech clearly addressed to the microphones 11, 21, 31 etc. A value is also given for level, to ensure speech directed to the microphone is preferred over background noise, and the level information can be passed to the spatialisation system to select a coding algorithm appropriate to the information in the speech. In order to detect

and process the speech in the signals they first need to be decoded in a decoder 231a (this may be dispensed with if the speech detection system 231b can operate with digitally encoded signals).

A voting algorithm 234 then selects which of the inputs 11, 21, 31 have
5 the clearest speech signals and controls a switch to direct each of those input channels 11, 21, 31 which have been selected to a respective one of the output channels 51, 52. Similar algorithms are used in Digital Circuit Multiplication Equipment (DCME) systems in international telephony circuits. Data relating the
10 correspondence between the input channels 11, 21, 31 and output channels 51, 52 is transmitted over the control channel 4. Alternatively, this data can be embedded in the encoded audio data.

When there are fewer talkers identified than there are available output channels 51, 52, signal quality can be improved by using a less compressed
15 digitisation scheme for those input channels selected, thereby using more than one output channel 51, 52 for each input channel selected. Telephone quality speech may be achieved at 8kbits/s, allowing eight talkers to be accommodated if the system has a 64kbit/sec capability. Should fewer talkers be detected, the 64kbit/s capability may be used instead to provide four 16 kbit/s audio channels, capable of
20 carrying 'good' quality speech, or a mixture of channels at different bit rates, to allow the coding rates to be selected according to the initial signal quality, or so that the main talker could be passed at higher quality than the other talkers. Layered coding schemes can be used to allow graceful switching between data rates.

25 The N-channel de-multiplexer and speech decoder 14 is shown in Figure 3. This receives the channels 51, 52, 53 etc carried in the audio downlink 5 and separates them in a demultiplexer 140. Each channel 51, 52, etc is then separately decoded in a respective decoder 141, 142, 143, etc for processing by the spatialiser 15. The decoders 141, 142, etc may operate according to different
30 processes according to the individual coding algorithms used, under the control of the control signals carried in the control channel 4.

A composite signal consisting of the summation of all input signals could also be transmitted. Such a signal could be used by users having monaural

receiving equipment, and may also be used by the spatialiser to generate an ambient background signal. Alternatively the spatialiser 15 may replace any of the channels 11, 21, 31 not selected by the concentrator 230, and therefore not represented in the N channel link 5, by "comfort noise"; that is low-level white noise, to avoid the aural impression of a void which would be occasioned by a complete absence of signal.

The customer equipment 10 can be implemented using a desktop PC. Readily available PC sound card technology can provide the audio interface and processing needed for the simpler spatialising schemes. The more advanced sound cards with built in DSP technology could be used for more advanced schemes. The spatialiser 15 can use any one of a number of established techniques for creating an artificial audio environment as detailed in the Hollier et al article referred to above. Spatialisation techniques may be summarised as follows. The simplest technique is "panning", where each signal is replayed with appropriate weighting via two or more loudspeakers such that it is perceived as emanating from the required direction. This is easy to implement, robust and may also be used with headphones.

"Ambisonic" systems are more complicated and employ a technique known as wavefront reconstruction to provide a realistic spatial audio percept. They can create very good spatial sound, but only for a very small listening area and are thus only appropriate for single listeners. For headphone listening, "binaural" techniques can be used to provide very good spatialisation. These use head-related transfer function (HRTF) filter pairs to recreate the soundfield that would have been present at the entrance to the ear canal for a sound emanating from any position in 3D space. This can give very good spatialisation and may be extended for use with loudspeakers, when it is known as "transaural". As with ambisonic systems, the correct listening position is very small. Any of these spatialisation techniques may be used with the present invention.

The output of several spatialisers may be combined as shown in Figure 4, which shows a spatialiser group for a stereophonic output having left and right channels 12L, 12R. Each channel 51, 52, 53 is fed to a respective spatialiser 151, 152, 153 which, under the control of a coefficient selector 150 control by the signals in the control channel 4, transmits an output 151L, 151R etc to each of a

series of combiners 15L, 15R. The processing used to create the outputs 151L, 151R etc is operated under the control of the signal 4 such that each channel appears as a virtual sound source, having its own location in the space around the listener.

5 The positions of virtual sources in three dimensional space could be determined automatically, or by manual control, with the user selecting the preferred positioning for each virtual sound source. For a video conference the positioning can be set to correspond with the appropriate video picture window. The video images may be sent by other means, or may be static images retrieved
10 from a local storage by the individual user.

If the spatialised sound is relayed via loudspeakers 12, rather than headphones, it will be necessary to prevent signals from the loudspeakers 12 being picked up by the microphone 11, re-transmitted and being heard as an echo at the distant sites 20, 30 etc. A technique for achieving this will be described later,
15 with reference to Figure 11.

Figure 5 shows an alternative arrangement to that of Figure 4, in which the spatialisation is computed in the conference 'bridge'. Each conference participant gets the same spatialised signals, thus simplifying the customer equipment. Figure 5 is similar in general arrangement to Figure 2, except that the
20 decoder 14 and spatialiser 15 are part of the exchange equipment 200. The output from the spatialiser 15 is passed to an encoder 18 which transmits the required number of audio channels (e.g. two for a stereo system) to each customer 10, 20, 30. This requires the number of channels in the downlink 5 to be equal to the number of audio channels in the spatialisation systems' outputs, instead of the
25 number selected by the concentrator (plus the control channel 4) as in the embodiment of Figure 2. It also simplifies the customer equipment 10. However, this arrangement requires all customer installations 10, 20, 30 to have similar spatialisation systems, and in particular the same number of audio channels. It would also be more difficult to remove a talker's own voice from the signal he
30 receives. Echo control would also be more complicated, and channel coding may degrade the spatialisation.

Conventional analogue connections could be included in the conference by providing each analogue connection 43, 45 to the 'bridge' 200 with an encoder

42, as shown in Figure 6, to provide an input 41 to the concentrator. The output 5 of the concentrator 230 is also decoded and combined in a unit 44 to provide a monaural conference signal 45 to the analogue user 40.

In the embodiments of Figures 2 to 4 and Figure 5, if loudspeakers are used there is a need to control acoustic feedback ("echo") between the loudspeaker 12 and the microphone 11, which will result in signals being retransmitted back into the system. This will result in each user hearing one or more delayed versions of each signal (including their own transmissions) arriving from the other users. For a monophonic system echo control is usually done using an echo canceller as shown in Figure 9. The echo signal, represented by D is caused by the acoustic path J between the loudspeaker 12 and microphone 11 of equipment 10 in room B. The cancellation is achieved in an echo control unit 16 by using an adaptive filter to create a synthetic model of the signal path such that the echo may be removed by subtraction. The signal E, returned to equipment 20 in room A, is now free of echoes, containing only sounds that originated in Room B. The optimum modelling of the acoustic path J is usually achieved by the adaptive filter in a manner such that some appropriate function of the signal E is driven towards zero. Echo control using adaptive filters in this manner is well known.

Multi-channel echo cancellation, as shown in Figure 10 for two channels, is more complex since there are two input channels 51, 52 and therefore two loudspeakers 12L, 12R. It is therefore necessary to model two echo paths K and L for each of the two return channels 3L, 3R. (The process is only shown for return channel 3L, using microphone 11L). Correct echo cancellation is only achieved if adaptive filters 161L, 162L model the signal paths K and L respectively. (Two further filters 161R, 162R are required for the other return channel 3R) However, it is not possible to find a correct model for each path K, L independently without some difficult and expensive signal processing as described in "*A better understanding and an improved solution to the specific problems of stereophonic echo cancellation*" (IEEE Transactions on speech and Audio processing, Vol 6, no 2 March 1998. Authors: J Benesty, D R Morgan and M M Sondhi).

The system described above with reference to Figure 4 employs linear artificial spatialisation techniques. Figure 11 shows how this, and the fact that the

echo from each loudspeaker 12L, 12R combines linearly at each microphone 11L, (11R, not shown), allows echo cancellation to be provided for each output channel 3L, (3R) by having a separate adaptive filter 161L, 162L, 163L, (161R, 162R, 163R) on each input channel 51, 52, 53. Thus the adaptive filter 161L will model
5 the combination of the spatialiser 151 for the channel 51, and the echo path between the loudspeakers 12L and 12R and the microphone 11L.

The invention could be applied to a conference situation in which there are several participants at each location, such as the video conference shown in Figure 7. Close microphones 11a, 11b, 11c, for example of the "tie-clip" type, are used
10 to pick up the sound from each individual talker, and a talker location system 60 is used to keep track of their spatial position. The talker location system 60 may comprise a system of microphones which can identify the positions of sound sources. Relating the position of a sound source to that of the tie clip microphone 11 currently in use makes it possible to learn the position of each talker by audio
15 means alone. Alternatively, the system may detect the position of each user by means such as optical recognition of a badge carried by each user. In either case, the position data is passed to the far end (Room B), where correct spatialisation is reconstructed, for output by loudspeakers 12L, 12M, 12R etc. This would achieve a true spatial conference and overcome the associated echo control problems,
20 since the "tie clip" microphones 31a, 31b, 31c have a limited range and will not detect the outputs from the loudspeakers 32 in the same room.

CLAIMS

1. A teleconferencing system comprising a conference bridge having a
5 multichannel connection to each customer equipment, at least one customer
equipment having means to separately process each channel to provide a plurality
of outputs, each output representing one of the other participants.
2. A system according to claim 1, wherein the customer equipment has
10 means to combine the outputs representing each participant to provide a
spatialised output in which each participant is represented by a virtual sound
source.
3. A system according to claim 1 or 2, wherein, the conference bridge
15 comprises a concentrator, having means to identify the currently active input
channels and to transmit only those active channels over the multichannel
connection, together with control information identifying the transmitted channels.
4. A system according to any preceding claim, wherein the channel
20 representing a given participant is excluded from the output provided to that
participant.
5. A system according to claim 4, comprising means in the customer
equipment for excluding the said channel from the processing.
25
6. A system according to claim 4, comprising means for excluding the said
channel from the multichannel transmission from the bridge to the respective
participant.
- 30 7. A system according to any preceding claim, the customer equipment
having echo cancellation means comprising means for detecting correlations
between the output signal from the customer equipment and the signals carried on
individual input channels to the customer equipment representative of other users,

such correlations being indicative of acoustic feedback at the customer equipment, and means for cancelling such feedback signals in the output signal.

8. A system according to claim 7, wherein the customer equipment
5 comprises, for each channel of the output signal, a plurality of adaptive filters, each adaptive filter being arranged to model the echo path between a respective input channel and the respective output channel, and
for each output channel there being provided a combiner for adding the outputs of the respective plurality of adaptive filters to generate an echo cancellation signal
10 for the respective output channel.

9. A method of providing teleconferencing services to a plurality of customer equipments, in which a multichannel connection is provided from a conference bridge to each customer equipment, in which at least one customer equipment
15 processes each channel separately to provide a plurality of outputs, each representing one of the other participants.

10. A method according to claim 9, wherein the conference bridge identifies the currently active input channels and transmits only those active channels over
20 the multichannel connection, together with control information identifying the transmitted channels.

ABSTRACT
TELECONFERENCING SYSTEM

A teleconferencing system comprises a conference bridge 100 having a
5 multichannel connection 5 to each customer equipment 10. The customer
equipment 10 has means 14 to separately process each channel 51, 52, 53 to
provide one output representing each of the other participants. These outputs can
be combined in a spatialiser 15 to provide a spatialised output 12 in which each
participant is represented by a virtual sound source. The conference bridge 100
10 comprises a concentrator 230, having means to identify the currently active input
channels and to transmit only those active channels over the multichannel
connection, together with control information identifying the transmitted channels.

TELECONFERENCING SYSTEM

This invention relates to audio teleconferencing systems. These are systems in which three or more participants, each having a telephone connection, can participate in a multi-way discussion. The essential part of a teleconference system is called the conference "bridge", and is where the audio signals from all the participants are combined. Conference bridges presently function by receiving audio from each of the participants, appropriately mixing the audio signals, and then distributing the mixed signal to each of the participants. All signal processing is concentrated in the bridge, and the result is monaural (that is, there is a single sound channel). This arrangement is shown in Figure 1, which will be described in detail later. The principal drawback with this system is that the audio quality is monophonic, generally poor, it is very difficult to determine which participants are speaking at any one time, especially when the number of participants is large.

According to the invention, there is provided a teleconferencing system comprising a conference bridge having a multichannel connection to each customer equipment, the customer equipment having means to separately process each channel to provide an output, preferably spatialised, representing each of the other participants. Preferably the conference bridge comprises a concentrator, having means to identify the currently active input channels and to transmit only those active channels over the multichannel connection, together with control information identifying the transmitted channels. This reduces the capacity required by the multichannel connection. The control information identifying the active channels may be carried in a separate control channel, or as an overhead on the active subset of channels. In a preferred arrangement the channel representing a given participant is excluded from the output provided to that participant. This may be achieved by excluding that channel from the processing in the customer equipment, but is preferably achieved by excluding it from the multichannel transmission from the bridge to that participant, thereby reducing further the capacity required by the multichannel connection.

Exemplary embodiments of the invention will now be described, by way of example, with reference to the drawings, in which:

Figure 1 illustrates a conventional teleconference system;

Figure 2 illustrates a spatial audio teleconference system according to one embodiment of the invention;

Figure 3 illustrates a N-channel speech decoder used in the embodiment of Figure 2;

5 Figure 4 illustrates a N-Channel audio spatialiser used in the embodiment of Figure 2;

Figure 5 illustrates a second embodiment of the invention;

Figure 6 illustrates how the invention may be used with conventional PSTN channels;

10 Figure 7 illustrates a variant of the invention for use with a video conference system;

Figure 8 illustrates a voice switched concentrator which may be used in the embodiments of the invention.

Figures 9, 10, and 11 illustrate various echo cancellation techniques.

15 In the conventional system illustrated in Figure 1 the conference bridge located in the exchange equipment 100 receives signals from the various customer equipments 10, (20, 30 not shown) in response to sounds detected by respective microphones 11, 21, 31 etc. These signals are transmitted over the telephone network (1), to the exchange 100 at which the bridge is established. Generally the
20 signals will travel by way of a local exchange (not shown) in which the analogue signals are converted to digital form, usually employing linear companding such as "A law" (as used for example in Europe) or "mu-Law" (as used for example in the United States of America) for onward transmission to the bridge exchange 100. On arrival at the bridge exchange 100, the bridge passes each incoming signal 11, 21,
25 31 through a respective digital converter 111, 112, 113 to convert them from A Law to linear digital signals, and then passes the linear signals to a digital combiner 120 to generate a combined signal. This combined signal is re-converted to A law in a further digital converter 110, and the resulting signal transmitted over the telephone network (2) to each customer equipment 10, (20, 30) for conversion to
30 sound in respective loudspeakers 12, 22, 32 etc. In this way the exchange equipment 100 acts as a "bridge" to allow one or more customer equipments 32 to connect into a simple two-way connection between customer equipments 10, 20.

The systems illustrated in Figures 2 to 8 replace the conventional conference bridge system of Figure 1 with a multicast system in which several channels can be transmitted to each participant, using a multi-channel link comprising an uplink 3, and a downlink comprising a control channel 4 and a digital audio downlink 5 comprising several channels 51, 52. Participants with suitable equipment can then process these channels 51, 52 in various ways as will be described.

The transmission medium used for the uplink 3 and downlink 4,5 can be any suitable medium. ISDN (Integrated Services Data Network) technology or LAN (Local Area Network) - respectively public and private data networks - are the favoured transmission options since they provide adequate data rate and low latency - delays due to coding and transmission buffering. However, they are expensive and so far have a low penetration in the market place. Internet Protocol techniques are more widely used, but have poor latency and unreliable data rates. Being packet systems, they are less suited to voice applications. It is also possible to use the conventional PSTN (public switch telephone system) with a speech band modem. The latest internet type modems provide up to 56kbit/s downstream (links 4,5: digital network down to the customer via local loop), and up to 28.8kbit/s upstream (link 3). They are low cost and are commonly bundled into PC packages. Ideally a system should be able to work with all of the above, and with standard analogue PSTN available as a backup.

The signal mixing can take place either in the user's terminal equipment, or in a centralised processing platform as shown in Figure 2. In Figure 2 the customer equipment 10 contains a microphone 11 and loudspeaker system 12 as before. However, the loudspeaker system 12 is a spatialised system - that is, it has two or more channels to allow sounds to appear to emanate from different directions. This may take the form of stereophonic headphones, or a more complex system such as disclosed in United States Patents 5533129 (Gefvert), 5307415 (Fosgate), article "*Spatial Sound for Telepresence*" by M.Hollier, D. Burraston, and A. Rimell in the *British Telecom Technology Journal*, October 1997 or the applicant's own pending European Patent Application 97304218.7 filed on 17th June 1997.

The output from the microphone 11 is encoded by an encoder 13 forming part of the customer equipment 10, and transmitted over the uplink 3 to the

exchange equipment 100. Here it is combined with the other input channels 21, 31 from the other participants into a concentrator 230 which combines the various inputs into an audio signal having a smaller number of channels 51, 52. These channels are transmitted over multiple-channel digital audio links 5 to the customer equipments 10, (20, 30) where they are first decoded by respective decoders 14, 24, 34 and provided to a spatialiser 15 for controlling the mixing of the channels to generate a spatialised signal in the speaker equipment 12.

The concentrator 230 selects from the input channels 11, 21, 31 those carrying useful information - typically those carrying speech, and passes only these over the return link 5. This reduces the amount of information to be carried. A control channel 4 carries data identifying which channels were selected. The spatialiser 15 uses data from the control channel to identify which of the original sound channels 11, 21, 31 it is receiving, and on which of the "N" channels 51, 52 in the audio link each original channel is present, and constructs a spatialised signal using that information. The spatialised signal can be tailored to the individual customer, for example the number of talkers in the spatialised system, the customer's preferences as to where in the spatialised system each participant is to appear to be located, and which channels to include; for example the original talker or a simultaneous translation. In particular, the user may exclude the channel representing his own input 11.

Transmission efficiency is achieved because only the active subset N of the total number of channels M are transmitted at any one time. The subset is chosen using a voice controlled dynamic channel allocation algorithm in the N:M concentrator 230. A possible implementation of this is shown in Figure 8. Each input channel 11, 21, 31 is monitored by a respective analyser 231, 232, 233. As shown for analyser 231, the signal is subjected to a speech detection and analysis process 231b. This detects whether speech is present on the respective input 11, and gives a confidence value, indicative of how likely the signal contains speech. This ensures that low-level background speech is given a lower weight than speech clearly addressed to the microphones 11, 21, 31 etc. A value is also given for level, to ensure speech directed to the microphone is preferred over background noise, and the level information can be passed to the spatialisation system to select a coding algorithm appropriate to the information in the speech. In order to detect

and process the speech in the signals they first need to be decoded in a decoder 231a (this may be dispensed with if the speech detection system 231b can operate with digitally encoded signals).

A voting algorithm 234 then selects which of the inputs 11, 21, 31 have
5 the clearest speech signals and controls a switch to direct each of those input channels 11, 21, 31 which have been selected to a respective one of the output channels 51, 52. Similar algorithms are used in Digital Circuit Multiplication Equipment (DCME) systems in international telephony circuits. Data relating the audio channels' content to the conference participants, and therefore the
10 correspondence between the input channels 11, 21, 31 and output channels 51, 52 is transmitted over the control channel 4. Alternatively, this data can be embedded in the encoded audio data.

When there are fewer talkers identified than there are available output channels 51, 52, signal quality can be improved by using a less compressed
15 digitisation scheme for those input channels selected, thereby using more than one output channel 51, 52 for each input channel selected. Telephone quality speech may be achieved at 8kbits/s, allowing eight talkers to be accommodated if the system has a 64kbit/sec capability. Should fewer talkers be detected, the 64kbit/s capability may be used instead to provide four 16 kbit/s audio channels, capable of
20 carrying 'good' quality speech, or a mixture of channels at different bit rates, to allow the coding rates to be selected according to the initial signal quality, or so that the main talker could be passed at higher quality than the other talkers. Layered coding schemes can be used to allow graceful switching between data rates.

25 The N-channel de-multiplexer and speech decoder 14 is shown in Figure 3. This receives the channels 51, 52, 53 etc carried in the audio downlink 5 and separates them in a demultiplexer 140. Each channel 51, 52, etc is then separately decoded in a respective decoder 141, 142, 143, etc for processing by the spatialiser 15. The decoders 141, 142, etc may operate according to different
30 processes according to the individual coding algorithms used, under the control of the control signals carried in the control channel 4.

A composite signal consisting of the summation of all input signals could also be transmitted. Such a signal could be used by users having monaural

receiving equipment, and may also be used by the spatialiser to generate an ambient background signal. Alternatively the spatialiser 15 may replace any of the channels 11, 21, 31 not selected by the concentrator 230, and therefore not represented in the N channel link 5, by "comfort noise"; that is low-level white noise, to avoid the aural impression of a void which would be occasioned by a complete absence of signal.

The customer equipment 10 can be implemented using a desktop PC. Readily available PC sound card technology can provide the audio interface and processing needed for the simpler spatialising schemes. The more advanced sound cards with built in DSP technology could be used for more advanced schemes. The spatialiser 15 can use any one of a number of established techniques for creating an artificial audio environment as detailed in the Hollier et al article referred to above. Spatialisation techniques may be summarised as follows. The simplest technique is "panning", where each signal is replayed with appropriate weighting via two or more loudspeakers such that it is perceived as emanating from the required direction. This is easy to implement, robust and may also be used with headphones.

"Ambisonic" systems are more complicated and employ a technique known as wavefront reconstruction to provide a realistic spatial audio percept. They can create very good spatial sound, but only for a very small listening area and are thus only appropriate for single listeners. For headphone listening, "binaural" techniques can be used to provide very good spatialisation. These use head-related transfer function (HRTF) filter pairs to recreate the soundfield that would have been present at the entrance to the ear canal for a sound emanating from any position in 3D space. This can give very good spatialisation and may be extended for use with loudspeakers, when it is known as "transaural". As with ambisonic systems, the correct listening position is very small. Any of these spatialisation techniques may be used with the present invention.

The output of several spatialisers may be combined as shown in Figure 4, which shows a spatialiser group for a stereophonic output having left and right channels 12L, 12R. Each channel 51, 52, 53 is fed to a respective spatialiser 151, 152, 153 which, under the control of a coefficient selector 150 control by the signals in the control channel 4, transmits an output 151L, 151R etc to each of a

series of combiners 15L, 15R. The processing used to create the outputs 151L, 151R etc is operated under the control of the signal 4 such that each channel appears as a virtual sound source, having its own location in the space around the listener.

5 The positions of virtual sources in three dimensional space could be determined automatically, or by manual control, with the user selecting the preferred positioning for each virtual sound source. For a video conference the positioning can be set to correspond with the appropriate video picture window. The video images may be sent by other means, or may be static images retrieved
10 from a local storage by the individual user.

 If the spatialised sound is relayed via loudspeakers 12, rather than headphones, it will be necessary to prevent signals from the loudspeakers 12 being picked up by the microphone 11, re-transmitted and being heard as an echo at the distant sites 20, 30 etc. A technique for achieving this will be described later,
15 with reference to Figure 11.

 Figure 5 shows an alternative arrangement to that of Figure 4, in which the spatialisation is computed in the conference 'bridge'. Each conference participant gets the same spatialised signals, thus simplifying the customer equipment. Figure 5 is similar in general arrangement to Figure 2, except that the
20 decoder 14 and spatialiser 15 are part of the exchange equipment 200. The output from the spatialiser 15 is passed to an encoder 18 which transmits the required number of audio channels (e.g. two for a stereo system) to each customer 10, 20, 30. This requires the number of channels in the downlink 5 to be equal to the number of audio channels in the spatialisation systems' outputs, instead of the
25 number selected by the concentrator (plus the control channel 4) as in the embodiment of Figure 2. It also simplifies the customer equipment 10. However, this arrangement requires all customer installations 10, 20, 30 to have similar spatialisation systems, and in particular the same number of audio channels. It would also be more difficult to remove a talker's own voice from the signal he
30 receives. Echo control would also be more complicated, and channel coding may degrade the spatialisation.

 Conventional analogue connections could be included in the conference by providing each analogue connection 43, 45 to the 'bridge' 200 with an encoder

42, as shown in Figure 6, to provide an input 41 to the concentrator. The output 5 of the concentrator 230 is also decoded and combined in a unit 44 to provide a monaural conference signal 45 to the analogue user 40.

In the embodiments of Figures 2 to 4 and Figure 5, if loudspeakers are used there is a need to control acoustic feedback ("echo") between the loudspeaker 12 and the microphone 11, which will result in signals being retransmitted back into the system. This will result in each user hearing one or more delayed versions of each signal (including their own transmissions) arriving from the other users. For a monophonic system echo control is usually done using an echo canceller as shown in Figure 9. The echo signal, represented by D is caused by the acoustic path J between the loudspeaker 12 and microphone 11 of equipment 10 in room B. The cancellation is achieved in an echo control unit 16 by using an adaptive filter to create a synthetic model of the signal path such that the echo may be removed by subtraction. The signal E, returned to equipment 20 in room A, is now free of echoes, containing only sounds that originated in Room B. The optimum modelling of the acoustic path J is usually achieved by the adaptive filter in a manner such that some appropriate function of the signal E is driven towards zero. Echo control using adaptive filters in this manner is well known.

Multi-channel echo cancellation, as shown in Figure 10 for two channels, is more complex since there are two input channels 51, 52 and therefore two loudspeakers 12L, 12R. It is therefore necessary to model two echo paths K and L for each of the two return channels 3L, 3R. (The process is only shown for return channel 3L, using microphone 11L). Correct echo cancellation is only achieved if adaptive filters 161L, 162L model the signal paths K and L respectively. (Two further filters 161R, 162R are required for the other return channel 3R) However, it is not possible to find a correct model for each path K, L independently without some difficult and expensive signal processing as described in "*A better understanding and an improved solution to the specific problems of stereophonic echo cancellation*" (IEEE Transactions on speech and Audio processing, Vol 6, no 2 March 1998. Authors: J Benesty, D R Morgan and M M Sondhi).

The system described above with reference to Figure 4 employs linear artificial spatialisation techniques. Figure 11 shows how this, and the fact that the

echo from each loudspeaker 12L, 12R combines linearly at each microphone 11L, (11R, not shown), allows echo cancellation to be provided for each output channel 3L, (3R) by having a separate adaptive filter 161L, 162L, 163L, (161R, 162R, 163R) on each input channel 51, 52, 53. Thus the adaptive filter 161L will model
5 the combination of the spatialiser 151 for the channel 51, and the echo path between the loudspeakers 12L and 12R and the microphone 11L.

The invention could be applied to a conference situation in which there are several participants at each location, such as the video conference shown in Figure 7. Close microphones 11a, 11b, 11c, for example of the "tie-clip" type, are used
10 to pick up the sound from each individual talker, and a talker location system 60 is used to keep track of their spatial position. The talker location system 60 may comprise a system of microphones which can identify the positions of sound sources. Relating the position of a sound source to that of the tie clip microphone 11 currently in use makes it possible to learn the position of each talker by audio
15 means alone. Alternatively, the system may detect the position of each user by means such as optical recognition of a badge carried by each user. In either case, the position data is passed to the far end (Room B), where correct spatialisation is reconstructed, for output by loudspeakers 12L, 12M, 12R etc. This would achieve a true spatial conference and overcome the associated echo control problems,
20 since the "tie clip" microphones 31a, 31b, 31c have a limited range and will not detect the outputs from the loudspeakers 32 in the same room.

CLAIMS

1. A teleconferencing system comprising a conference bridge having a
5 multichannel connection to each customer equipment, at least one customer
equipment having means to separately process each channel to provide a plurality
of outputs, each output representing one of the other participants.
2. A system according to claim 1, wherein the customer equipment has
10 means to combine the outputs representing each participant to provide a
spatialised output in which each participant is represented by a virtual sound
source.
3. A system according to claim 1 or 2, wherein, the conference bridge
15 comprises a concentrator, having means to identify the currently active input
channels and to transmit only those active channels over the multichannel
connection, together with control information identifying the transmitted channels.
4. A system according to any preceding claim, wherein the channel
20 representing a given participant is excluded from the output provided to that
participant.
5. A system according to claim 4, comprising means in the customer
equipment for excluding the said channel from the processing.
- 25 6. A system according to claim 4, comprising means for excluding the said
channel from the multichannel transmission from the bridge to the respective
participant.
- 30 7. A system according to any preceding claim, the customer equipment
having echo cancellation means comprising means for detecting correlations
between the output signal from the customer equipment and the signals carried on
individual input channels to the customer equipment representative of other users,

such correlations being indicative of acoustic feedback at the customer equipment, and means for cancelling such feedback signals in the output signal.

8. A system according to claim 7, wherein the customer equipment
5 comprises, for each channel of the output signal, a plurality of adaptive filters, each adaptive filter being arranged to model the echo path between a respective input channel and the respective output channel, and
for each output channel there being provided a combiner for adding the outputs of the respective plurality of adaptive filters to generate an echo cancellation signal
10 for the respective output channel.

9. A method of providing teleconferencing services to a plurality of customer equipments, in which a multichannel connection is provided from a conference bridge to each customer equipment, in which at least one customer equipment
15 processes each channel separately to provide a plurality of outputs, each representing one of the other participants.

10. A method according to claim 9, wherein the conference bridge identifies the currently active input channels and transmits only those active channels over
20 the multichannel connection, together with control information identifying the transmitted channels.

ABSTRACT
TELECONFERENCING SYSTEM

A teleconferencing system comprises a conference bridge 100 having a
5 multichannel connection 5 to each customer equipment 10. The customer
equipment 10 has means 14 to separately process each channel 51, 52, 53 to
provide one output representing each of the other participants. These outputs can
be combined in a spatialiser 15 to provide a spatialised output 12 in which each
participant is represented by a virtual sound source. The conference bridge 100
10 comprises a concentrator 230, having means to identify the currently active input
channels and to transmit only those active channels over the multichannel
connection, together with control information identifying the transmitted channels.
